

Assignment 5 (26.11.2021)

Handin until: Friday, 03.12.2021, 00:00

Exercise 1: Polynomials

[20 Points]

What is a Number? Haskell's type system answers this question in a simple way. A number—i.e. an instance of type class `Num`—is anything that can be added, subtracted, multiplied, negated, and so on¹:

```
1 | Prelude> :info Num
2 | class Num a where
3 |   (+) :: a -> a -> a
4 |   (-) :: a -> a -> a
5 |   (*) :: a -> a -> a
6 |   negate :: a -> a
7 |   abs :: a -> a
8 |   signum :: a -> a
9 |   fromInteger :: Integer -> a
10 | {-# MINIMAL (+), (*), abs, signum, fromInteger, (negate | (-)) #-}
11 | -- Defined in 'GHC.Num'
12 | [...]
```

Can a *polynomial* be such a number? Sure! Polynomials can be added, subtracted, and multiplied just like any other number. In this exercise we will implement a representation for polynomials and make them an instance of `Num`.

A polynomial is a sequence of *terms*. Each term has a *coefficient* and a *degree*. For example, the polynomial $x^2 + 5x + 3$ has three terms, one of degree 2 with coefficient 1, one of degree 1 with coefficient 5, and one of degree 0 with coefficient 3. Our representation of a polynomial in *Haskell* will be a list of coefficients, whose degrees corresponds to their position (0,1,...) in the list:

```
1 | data Poly a = P [a]
```

For example, the polynomial $x^2 + 5x + 3$ is represented as `P [3,5,1]`. The type of coefficients is polymorphic; in particular, polynomials over integers, floats, or booleans can be represented. However, most of the rest of this exercise only applies to polynomials with *numeric coefficients*. You may thus restrict the type to `Num a => Poly a` whenever necessary.

1. First, define a value `x` representing the polynomial $f(x) = x$.

```
1 | x :: Num a => Poly a
```

2. Write an instance of class `Eq` for polynomials with numeric coefficients. Note that it is *not* possible to simply compare the lists. Remember that you don't have to implement function `(/=)` explicitly; it has a default implementation in terms of `(==)`.

Examples:

```
1 | P [1,2,3,0] == P [1,2,3] == True
2 | P [1,2]    /= P [1,2,3] == True
```

3. Polynomials, e.g. `P [-3,2,0,-1]`, should be displayed in the following—human readable—form:

```
1 | (-x^3) + 2x + (-3)
```

- Terms are displayed as cx^e where c is the coefficient and e is the exponent. If e is 0, only c is displayed. If e is 1, the exponent is not displayed (cx).
- Terms are separated by the `+` sign with a single space on each side.
- Terms are listed in *decreasing* order of their degree.

¹Note that division is not included. There is another type class, `Integral`, for that.

- Terms with a coefficient 0 are not displayed, unless the whole polynomial equals 0.
- The coefficient 1 is not displayed, unless the degree is 0.
- Terms with negative coefficients (assume `Ord a => Poly a` to test for $c < 0$) can either be put in parentheses, or the leading operator + can be replaced by -. ² Both versions are fine.
Example: $(-x^3) + 2x + (-3)$ or $-x^3 + 2x - 3$.

Make `Poly a` an instance of class `Show` (implement function `show :: Poly a -> String`), following the specification above.

Examples:

```
1 show (P [1,0,0,2]) == "2x^3 + 1"
2 show (P [0,-1,2]) == "2x^2 + (-x)"
```

- The first function of a `Num` instance for polynomials (with numeric coefficients) is `fromInteger :: Num a => Integer -> Poly a`. An integer c is a polynomial of degree 0 with coefficient c . Remember that you have to convert the `Integer` to a value of type `Num a => a` before you can use it as coefficient.

Begin with an instance declaration for `Num a => Num (Poly a)` and define `fromInteger`. The declaration is to be completed with all other necessary function definitions in the following.

- Addition on polynomials is fairly simple. All you have to do is to add the coefficients pairwise for each term of the same degree in the two polynomials. For example $(x^2 + 5) + (2x^2 + x + 1) = 3x^2 + x + 6$.

Write a function `plusP` which adds one polynomial to a second:

```
1 plusP :: Num a => Poly a -> Poly a -> Poly a
```

Note that the type signature for `plusP` has the constraint that `a` has a `Num` instance. Because of that you can use all of the usual `Num` functions (i.e. `(+)`) on the coefficients of your polynomials.

Complete the definition of `(+)` in your instance using `plusP`. Examples:

```
1 P [5,0,1] + P [1,1,2] == P [6,1,3]
2 P [1,0,1] + P [1,1] == P [2,1,1]
```

- To multiply two polynomials, each term in the first polynomial must be multiplied by each term in the second polynomial.

Implement a function

```
1 timesP :: Num a => Poly a -> Poly a -> Poly a
```

Complete the definition of `(*)` in your instance using `timesP`. Example:

```
1 P [1,2,3] * P [2,2] == P [2,6,10,6]
```

Proceed as follows:

- Multiply the second polynomial with each coefficient c_0, c_1, \dots in the first polynomial separately.

```
1 P [1,2,3] * P [2,2]: 1 * P [2,2] = P [2,2],
2                       2 * P [2,2] = P [4,4],
3                       3 * P [2,2] = P [6,6]
```

- Shift the result of c_i i decimal places to the right.

```
1 P [1,2,3] * P [2,2]: shift 0 $ 1 * P [2,2] = P [2,2],
2                       shift 1 $ 2 * P [2,2] = P [0,4,4],
3                       shift 2 $ 3 * P [2,2] = P [0,0,6,6]
```

- Calculate the sum of all intermediate results.

```
1 P [1,2,3] * P [2,2] = P [2,2] + P [0,4,4] + P [0,0,6,6] = P [2,6,10,6]
```

²If there is no leading operator a simple unary leading - without parentheses is fine, too.

7. Write a definition of `negate` for your instance. This function should return the negation of a polynomial. In other words, the result of negating all of its terms. For example: $3x^2 - x + 6 \equiv -(3x^2 - x + 6) \equiv -3x^2 + x - 6$ or `negate (P [6,-1,3]) ≡ P [-6,1,-3]`

Note that with the definition of `(+)` and `negate` we get `(-)` for free, without having to implement it.

8. Write a definition of `abs :: a -> a` for your instance which turns all coefficients to positive numbers.³ For example: `abs (P [6,-1,3]) ≡ P [6,1,3]`

9. Write a definition of `signum :: Poly a -> Poly a` for your instance.

The “sign” of a polynomial $P = c_n x^{e_n} + \dots + c_1 x^{e_1}$ ($c_n \neq 0$, if $n > 1$) shall be defined as:

$$\text{signum}(P) = \begin{cases} +1 & , \quad c_n > 0 \\ 0 & , \quad c_n = 0 \\ -1 & , \quad c_n < 0 \end{cases}$$

Note: You may have to add more type class constraints to the context of your instance declarations.

Examples:

```
1 | signum $ P [3,-2,0,1]  ≡ P [1]
2 | signum $ P [3,-2,0,-1] ≡ P [-1]
```

10. **Bonus (optional):** Note that the `Prelude` documentation for `signum` says:

“The functions `abs` and `signum` should satisfy the law: `abs x * signum x == x`”

Can you give an alternative implementation of `abs`—possibly different to the one we implemented in the previous subtask—such that the law is satisfied?

Now that we have completed the `Num` instance for polynomials, we can stop using coefficient list syntax. The polynomial $x^2 + 5x + 3$ can now directly be written as

```
1 | x^2 + 5*x + 3
```

This is a composition of expressions of type `Poly Int`, using the overloaded operators of `Num (Poly Int)`, next to value `x` (recall your definition in 1.) and the operator `(^)`, which is also defined in terms of the `Num` instance:

```
1 | Prelude> :t (^)
2 | (^) :: (Num a, Integral b) => a -> b -> a
```

³This definition is far away from a mathematical *absolute value* function for polynomials which would have to be a mapping from polynomials to numbers of \mathbb{R} . However, it fits the given signature for `abs` and might be a reasonable and practical interpretation of what an `abs`-function for `Poly a` in Haskell might be associated with.
